Abstract. We present results from a project conducted by the Survey Science Center of the XMM-Newton satellite and aiming at the identification and characterisation of serendipitous EPIC sources at low galactic latitudes. Deep multi-colour optical imaging and spectroscopic observations have been obtained in the framework of several observing campaigns carried out at ING, CFHT and ESO. These observations have led to a number of optical identifications, mostly with active stars. We describe the identified source content at low galactic latitudes and compare stellar populations properties at low and high galactic latitudes with those expected from stellar X-ray count models.

1. Introduction

Thanks to their excellent sensitivity, good image quality over a wide field of view (30') and wide energy range (0.2-12 keV) the EPIC cameras on board XMM-Newton allow X-ray surveys with an unprecedented combination of large area and depth. This potential was recognised by ESA in setting up a dedicated XMM-Newton Survey Science Center (SSC) to facilitate the exploitation of the XMM-Newton Serendipitous Sky Survey by providing a public archive of data products and carrying out a carefully coordinated follow-up programme to characterise the overall X-ray source population (Watson et al. 2001).

In this paper we present results from an ongoing SSC optical campaign whose aim is to provide a reference frame for the characterisation of all low galactic latitude EPIC serendipitous detections. Beyond proper identification and classification, our objective is to study source properties, quantify their relative populations and contributions to the overall soft and hard X-ray galactic emission. XMM-Newton measurements are not strongly biased by interstellar extinction, as were earlier studies based on ROSAT observations restricted to the softer 0.5-2 keV band. Although similar in X-ray flux to the deepest ROSAT pointings, the galactic landscape unveiled by XMM-Newton differs from that seen by ROSAT. Opening new parameter spaces the present survey offers the possibility to reveal completely new classes of sources.

Many individual source types are known to contribute to the galactic X-ray source demography in the medium to low X-ray luminosity regime (10^{28-36} erg s⁻¹). These in-

clude, late and early-type stars, cataclysmic variables (CVs), RS CVns and various species of X-ray binaries. Other kinds of rare emitters such as isolated neutron stars or low-luminosity but long-lived evolutionary states of classical XRBs may be found.

2. Observational material

Target fields (see Table 1) were selected for their good X-ray quality (depth and low background) and chosen in directions void of extended diffuse emission or bright sources. We also avoided atypical regions such as known star forming complexes. Mainly based on EPIC pn data, source detections were visually screened and positions were in most cases corrected for residual attitude errors by cross-correlating them with large optical catalogues. In order not to exclude extreme sources we retained detections in all energy bands.

Optical data were collected in the framework of the AXIS project (Barcons et al. 2002) performed at the Observatorio del Roque de los Muchachos in the Canary Islands and from programmes conducted at CFHT and at ESO. The wide field camera at INT, the CFH12K at CFHT and the WFI at ESO-MPG 2.2m provided wide-field imaging in the g', r', i', z, R, I and H α / H α continuum from which high spatial resolution mapping of the error circles and candidate priorities for spectroscopic observations were derived. Medium to low resolution spectroscopy was obtained on 4m-class telescopes using multi-fiber instruments (WHT/WYFFOS) or long slit spectrographs (WHT/ISIS, ESO 3.6m/EFOSC2).

The total area surveyed so far is ~ 0.8 deg². With exposure times in the range of 10 to 30 ksec we reach flux limits of $\sim 4 \cdot 10^{-15}$ erg cm⁻² s⁻¹ in the 0.5 to 2.0 keV soft band and of $\sim 3 \cdot 10^{-14}$ erg cm⁻² s⁻¹ in the 2 to 10 keV

Table 1. Galactic target fields

Field	RA	Dec	l	b	Gal N_H
WR 110	18h07	-19°23'	10.8°	+0.4°	$5.5 \cdot 10^{22}$
Ridge3	18h27	-11°29'	20.3°	+0.0°	$1.1 \cdot 10^{23}$
G21.5-09	18h33	-10°34'	21.5°	-0.9°	$9.0 \cdot 10^{22}$
Z And	23h33	+48°49'	109°	-12.1°	$1.4 \cdot 10^{21}$

hard energy range. The present survey can thus be qualified as medium sensitivity in being about 10 times shallower than the Chandra deep galactic survey of Ebisawa et al. (2002) but 10 times deeper than the medium ROSAT survey of Morley et al. (2001) or than the faint ASCA galactic plane survey of Sugizaki et al. (2001).

In order to compare stellar population properties in the galactic plane with those observed at high galactic latitudes we also use stellar identifications obtained in the course of the high $|b|$ AXIS programme (Barcons et al. 2002). The sample consists of 34 stars extracted from 18 XMM-Newton fields ($|b| = 23^\circ - 80^\circ$, average value 50°) in a total survey area of 2.3 deg^2 . The flux limit is $2 \cdot 10^{-14} \text{ erg cm}^{-2} \text{ s}^{-1}$ in the 0.5 to 4.5 keV band slightly above that used in the galactic plane.

3. Identification Strategy

Identification of XMM-Newton sources in the Milky Way can be made difficult by optical crowding. Matching the pattern of EPIC sources with the USNO A-2 catalogue and then correcting for residual attitude errors can shrink the 90% confidence level error radius down to $\sim 2.5''$. However if field stellar density is too high, no such adjustment can be made and the 90% confidence level error radius remains of the order of $4.5''$. Based on our wide field imaging we estimate that at $b \sim 0^\circ$ the probability to find at random a star brighter than $R \sim 16 - 17$ in a typical EPIC error circle is low enough (5%) that we can accept the identification on the basis of positional coincidence. However, in many cases this argument cannot be used and we have to collect optical spectra of typically 3-4 candidates brighter than $R \sim 22$ before possibly finding a reliable identification. At the sensitivity of our survey, stellar counterparts fainter than $R \sim 16 - 17$ are mostly late K-M stars. Balmer emission is found in all active M stars and in a fraction of the most active K stars. Cataclysmic variables and Be/X-ray binaries are also $H\alpha$ emitters. Our narrow band $H\alpha$ and $H\alpha$ continuum imaging together with broad band colour information can thus be used to efficiently prioritize optical candidates for spectroscopy (Herent et al. 2002). We also discarded sources with hardness ratios consistent with those expected from an absorbed background AGN and with only faint optical candidates in the error circle. This selection is efficiently done in directions of high absorption and still leaves a large range of possible N_H (or intrinsic spectral hardness) for galactic objects.

**Fig. 1.** Optical spectrum of a faint accreting candidate in the field of WR 110

4. Optical identifications

We list in Table 2 the statistics of optical identifications in each field and for the entire galactic sample. The limiting magnitude defined here as the faintest magnitude at which we can detect emission lines typical for a CV or a Me star depends on the instrumental setting and is $R \sim 19$ for the G21.5-09 and Z And fields and $R \sim 21$ for the Ridge 3 and WR 110 fields. The vast majority of optical identifications are with active coronae. Because of the relatively high galactic latitude and correspondingly low N_H it was still possible to spectroscopically identify two AGN in the Z And field. At lower latitudes, galactic absorption becomes too large for our instrumentation. The only low b extragalactic source is in the field of G21.5-09 (XMMU J183225.4-103645, Nevalainen et al. 2001) and was identified as an X-ray bright cluster of galaxies seen through over 50 magnitudes of absorption in the visual on the basis of X-ray source extent and energy distribution.

4.1. Accreting candidates

In three cases, we detect X-ray emission from a Be star at a level which is slightly above that expected for 'normal' early type stars (Cassinelli et al. 1994). In addition to the case of SS 397 already mentioned in Motch (2000), we find excess X-ray emission from USNO 0750-13549725 which is the brightest star in the open cluster NGC 6649. At a distance of 1.6 kpc and with $E(B-V) = 1.38$ (Turner 1981) the X-ray luminosity is $\sim 4 \cdot 10^{32} \text{ erg s}^{-1}$ (0.5 - 7.5 keV). Finally, we detect $H\alpha$ emission from a faint red star ($R = 22.0$, $R-I = 2.6$) in the field of WR 110. The absence of TiO features and the colour index indicate high interstellar absorption (see Fig. 1). If the counterpart is an intrinsically blue object then A_V is of the order of 12.5 or $N_H = 2.2 \cdot 10^{22} \text{ cm}^{-2}$, i.e. about half of the total expected galactic absorption in that direction. The high interstellar reddening and accordingly large distance rules out a CV nature. A Be star identification seems likely and the star would then be at $\sim 12 \text{ kpc}$ implying an X-ray luminosity of $1.3 \cdot 10^{33} \text{ erg s}^{-1}$ (0.5 - 7.5 keV). Such modest X-ray luminosity excesses may be in part due to errors on the reddening.

Table 2. Statistics of optical identifications at low galactic latitudes

Field	G21.5-09	Ridge3	WR 110	Z And	Total
b	-0.9°	0.0°	+0.4°	-12.1°	
Area	0.27	0.18	0.18	0.18	0.81
Number of sources	77	30	58	38	203
Stellar coronae	15 (19%)	14 (47%)	29 (50%)	9 (24%)	67
Accreting candidates	2	0	1	0	3
Extragalactic sources	1	0	0	2	3
Unidentified	59 (77%)	16 (53%)	28 (48%)	27 (71%)	130

We note however, that the numerous Be + WD systems predicted by binary evolution theory could well be emitting in this range of luminosities (see Raguzova 2001 and references therein).

4.2. The stellar population

At very low galactic latitudes, the fraction of sources identified with active coronae varies very significantly with pointing direction. Whereas in the WR 110 and Ridge 3 fields stellar coronae account for about half of the X-ray sources, the fraction is only 19% in the field of G21.5-09 in spite of the fact that source density is similar to that of WR 110. Such a variance is not unexpected and could reflect the presence of a higher 'local' absorption in the field of G21.5-09 preventing spectroscopic identification of the globally optically dimmer stellar population.

Spectral types, distances and luminosities were derived for most stellar identifications in the WR 110 and Ridge 3 fields as well as for the high galactic latitude sample (see Table 3).

In both $b \sim 0^\circ$ fields, the mean B-V excess of X-ray active stars is about 0.6 (or $N_H \sim 3.5 \cdot 10^{21} \text{ cm}^{-2}$). We detect active coronae up to 500 pc in Ridge 3 and 1 kpc in WR 110.

At the flux level considered here ($\sim 4 \cdot 10^{-15} \text{ erg cm}^{-2} \text{ s}^{-1}$ in the 0.5 to 2.0 keV band), the low $|b|$ active star population displays a distribution in spectral types which is not statistically different from that seen at high $|b|$. The low latitude ROSAT survey (Motch et al. 1997) also exhibits a similar spectral type distribution in spite of a factor 25 lower sensitivity (see Table 3). At low and high latitudes, the observed distributions match well those expected from X-ray count models (Guillout et al. 1996, Guillout & Motch 2002). In particular, we are not yet in a flux regime faint enough for M stars to dominate at high latitudes. Deeper surveys could however reveal this effect.

The distribution in X-ray luminosity of the two $b \sim 0^\circ$ stellar samples and of the $|b| \sim 50^\circ$ sample is shown in Fig. 2. In the galactic plane, Lx peaks between 10^{29} and $10^{30} \text{ erg s}^{-1}$, typical for stars with ages of the order of that of the Pleiades ($\leq 10^8 \text{ yr}$, see e.g. Micela et al. 1990). In contrast, the Lx distribution at high $|b|$ shows two peaks, one between 10^{28} and $10^{29} \text{ erg s}^{-1}$ and one at very high Lx between 10^{30} and $10^{31} \text{ erg s}^{-1}$. The low luminosity component has a solar like X-ray luminosity typical for the relatively old stellar population preferentially detected at high latitudes. The origin of the high luminosity component is not yet clear. It

could be due to close binaries such as RS CVns for which synchronized rotation maintains a strong X-ray luminosity over a long time. Alternatively, a fraction of these high Lx stars could be misidentifications.

Table 3. Distribution in spectral types of active coronae (percents)

XMM-Newton : Observed and Model prediction				
	M	K	G	F+A
$ b \sim 0^\circ$	28.6 ± 6.4	32.7 ± 6.7	22.4 ± 6.0	16.3 ± 5.3
	24	25	31	20
$ b \sim 50^\circ$	29.4 ± 7.8	17.6 ± 6.5	23.5 ± 7.3	29.4 ± 7.8
	27	19	29	25
ROSAT all-sky survey				
	M	K	G	F+A
$ b \sim 0^\circ$	19.0 ± 6.0	23.8 ± 6.5	26.2 ± 6.8	30.5 ± 7.1

We also show in Fig. 3 the log N(>S)-log S curve for stars at low and high galactic latitudes. At EPIC pn count rates of a few 10^{-3} cts/s (0.5 - 2.0 keV), the density of active stars is about 10 times larger in the galactic plane (here only Ridge 3 and WR 110 fields) than at high b . Predictions of the stellar population models for $b = 0^\circ$ and 50° fit rather well the observed curves. One should however keep in mind the large density variance observed at low latitudes. As argued above, part of this scatter could be due to complex absorption structures which are not yet taken into account in the X-ray count model. X-ray luminous old binaries may also account for a sizeable fraction of the population. Clearly more stellar identifications are needed in order to build really representative samples.

5. Conclusions

Not unexpectedly, our observations confirm the well known concentration of young active stars in the galactic plane. Because of the steep decline of coronal activity with age, X-rays highlight the young stellar population. Whereas at optical wavelength stars younger than 1 Gyr make up only $\sim 10\%$ of the total stellar population and do not exhibit marked signatures, they account for about half of the X-ray detections, the exact fraction depending on galactic latitude and limiting flux. The large sensitivity of XMM-Newton allows to sample young stellar populations up to 1 kpc or more as

Fig. 2. Distribution in X-ray luminosity of active coronae. Left: $|b| \sim 0^\circ$. Right: $|b| \sim 50^\circ$

demonstrated in the WR110 field. At these distances, a number of effects expected from X-ray stellar populations models become readily visible and can be used to put very significant constraints on the dynamical properties of young stars, especially the evolution of scale height with age, and on the SFR during the last ~ 2 Gyr. Among these effects are the sharp decrease of number count with increasing galactic latitudes, the rising fraction of old stars at high b and the increasing fraction of M stars at faint fluxes.
